26 Abstract

27 Plexins are semaphorin receptors that play essential roles in mammalian neuronal axon guidance and 28 in many other important mammalian biological processes. Plexin signaling depends on a semaphorin-29 induced dimerization mechanism, and is modulated by small GTPases of the Rho family, of which 30 RND1 serves as a plexin activator yet its close homolog RhoD an inhibitor. Using molecular 31 dynamics (MD) simulations we showed that RND1 reinforces the plexin dimerization interface 32 whereas RhoD destabilizes it due to their differential interaction with the cell membrane. Upon 33 binding plexin at the Rho-GTPase binding domain (RBD), RND1 and RhoD interact differently with 34 the inner leaflet of the cell membrane, and exert opposite effects on the dimerization interface via an 35 allosteric network involving the RBD, RBD linkers, and a buttress segment adjacent to the 36 dimerization interface. The differential membrane interaction is attributed to the fact that, unlike 37 RND1, RhoD features a short C-terminal tail and a positively charged membrane interface.

38 Introduction

Plexins are a family of nine single-pass transmembrane receptor proteins including plexin A1–4, B1– 3, C1 and D1. Plexins are best known as the receptors of extracellular semaphorin ligands (Nishide and Kumanogoh, 2018) that are guidance cues for neuronal axons. Plexins also help regulate other essential biological processes such as cell migration, angiogenesis and immune responses (Sakurai et al., 2012; Takamatsu and Kumanogoh, 2012). Aberrant plexin activity is associated with a plethora of diseases including neurological disorders and cancer metastasis (Gu and Giraudo, 2013; Tamagnone, 2012; Yaron and Zheng, 2007).

46 Plexin architecture is conserved across the family. Plexin consists of a large multi-domain 47 extracellular module including the ligand-binding Sema domain, a single-pass transmembrane helix, 48 and an intracellular module that includes a GTPase activating protein (GAP) domain and a Rho-49 family GTPase binding domain (RBD) (Figure 1A). In plexin signaling, semaphorin binds at the 50 extracellular module, which leads to activation of the GAP domain. Structures (Janssen et al., 2010; 51 Kuo et al., 2020; Liu et al., 2010; Nogi et al., 2010) showed that a semaphorin mediates plexin 52 dimerization: a semaphorin dimer interacts with two plexins at the extracellular module, and this 53 extracellular dimerization leads to dimerization at the intracellular module (Figure 1B), and in turn 54 activation of the GAP domain for the substrate Rap GTPases (Wang et al., 2012). The dimerization 55 stabilizes the active conformation of the so-called activation segments of the GAP domains, which 56 otherwise adopts an inactive conformation that precludes Rap binding to the GAP domain (Wang et 57 al., 2013). In plexin signaling, the GAP activity switches off the signaling of plexin substrate Rap by 58 catalyzing its GTP hydrolysis and converting it from the GTP-bound state to the GDP-bound state. 59 We will refer to GTPases such as Rap, which bind at the active site of the GAP domain, substrate 60 GTPases.

Besides the GAP domain, the intracellular module of plexin includes an RBD domain that binds Rhofamily GTPases. The RBD of PlexinB1 has been shown to bind Rac1, Rac2, Rac3, Rnd1, Rnd2, Rnd3 and RhoD, but not RhoA, Cdc42, RhoG or Rif (Fansa et al., 2013). These Rho-family GTPases to various degrees serve as regulators in plexin activation. To distinguish them from the GAPbinding substrate GTPases such as Rap, we refer to these RBD-binding GTPases as regulatory GTPases.

67 The Rho-family regulatory GTPases play important roles in plexin regulation from the intracellular 68 environment. Over-expression of Rac1 leads to higher cell surface expression of plexin and enhances 69 plexin interaction with semaphorin, suggesting that Rac1 acts as an upstream activator of plexin 70 (Vikis and H., 2002). Binding of over-expressed RND1 to plexin triggers cell collapse in the absence 71 of semaphorin, suggesting that RND1 is a more potent activator than Rac1 for plexin (Zanata et al., 72 2002). Simultaneous extracellular binding of semaphorin and intracellular RBD binding of certain 73 regulatory GTPases appear to be a prerequisite for full activation of at least some plexins (Bell et al., 74 2011), but RBD binding with some other regulatory GTPases of the Rho family attenuates plexin 75 activity. RhoD and RND1 are two such regulatory GTPases. RhoD binds plexin RBD with similar 76 affinity as RND1 (Fansa et al., 2013), but it strongly inhibits plexin signaling (Zanata et al., 2002) 77 rather than activates it.

The structural mechanism of the antithetic effects of RhoD and RND1 on plexin signaling, however, remains elusive. Activity assays in solution showed that the Rho-family GTPases do not alter the GAP activity of plexin either in the monomeric or the active dimer state (Wang et al., 2012). RND1 is anchored to the membrane by a C-terminal amphipathic helix (Figure 1C) and RhoD by lipidation of a cysteine at the C-terminal tail (Figure 1-figure supplement 1), and the membrane may play an important role in their plexin regulation. Resolved complex structures of plexin RBD with different Rho-family GTPases, such as RND1 (PDB 2REX and 3Q3J) and Rac1 (Wang et al., 2012), showed 85 that the RBD binds with these GTPases in a similar mode. The structure of plexin RBD in complex 86 with RhoD is not available, but data from NMR chemical shift analyses as well as binding assays 87 with RhoD in different nucleotide states and mutants of plexin RBD together suggested that the 88 binding mode is similar (Fansa et al., 2013; Tong et al., 2007; Zanata et al., 2002). The crystal 89 structures and other biophysical data all suggest that the RBD domain does not undergo substantial or 90 global conformational changes upon binding with Rho-family GTPases (Bell et al., 2011; Tong et al., 91 2007; Wang et al., 2012). Modulations of plexin activity from Rho-family GTPases thus are unlikely 92 to be mediated by major conformational changes within the RBD domain.

93 To understand the apparent paradox regarding the antithetic effects of RND1 and RhoD on plexin 94 activation, we determined the crystal structure of the RhoD/plexin B2-RBD complex, which 95 confirmed that the RBD binding mode of RhoD is similar to that of other Rho-family regulatory 96 GTPases. We then modeled and simulated plexin A4 complexed with RND1 or RhoD (Figure 1C), to 97 investigate the structural mechanisms underlying RND1 as an activator and RhoD as an inhibitor in 98 plexin regulation. The simulations suggested that RND1 binding is compatible with the dimerization 99 of plexin A4 while RhoD binding is likely disruptive to the dimerization. The simulations generated 100 two distinct modes of interactions of RND1 and RhoD with the membrane: RND1 interacts with the 101 membrane loosely and its long C-terminal tail serves as a flexible tether to the membrane (Figure 102 1D), whereas RhoD interacts with the membrane in a specific manner using a positively charged 103 membrane interface (Figure 1E), which is absent in RND1. As a result, RND1 binding strengthens 104 plexin dimerization by stabilizing the RBD position with respect to the GAP domain and in turn 105 stabilizing the adjacent dimerization interfaces, while RhoD distorts the RBD position and hinders 106 plexin dimerization.

108 **Results**

109 Crystal structure of the complex between RhoD and the plexin B2-RBD domain

110 Complex structures of the RBD domain with plexin activators such as RND1 or Rac1 have been 111 previously resolved. To experimentally determine the binding mode between plexin and RhoD, a 112 negative plexin regulator, we screened various combinations of RhoD and the intracellular region of 113 plexin family members from different species for crystallization, which resulted in crystals of the 114 complex of mouse plexin B2 and human RhoD bound to the GTP analogue GMP-PNP. Analyses of 115 the diffraction data suggested that plexin B2 degraded during the incubation in crystallization drops, 116 and the crystals only contained the complex between RhoD and the RBD of plexin B2. We solved the 117 structure to 3.1 Å resolution by molecular replacement (Supplementary File 1; See methods for 118 details). The asymmetric unit of the crystal contains two RhoD molecules, each of which binds to one 119 plexin B2 RBD molecule. Surprisingly, the two RBD domains form a domain-swapped dimer in the 120 structure, with the N-terminal portion of one molecule fold together with the C-terminal portion of 121 the other (Figure 2-figure supplement 1). This domain-swapped dimer is likely a crystallization 122 artifact because it cannot form in the context of a plexin dimer (Wang et al., 2013), in which the two 123 RBD domains are far apart from one another (Figure 1B). We therefore consider each RBD domain 124 formed by the two halves of the two molecules as a representative of one intact, unswapped RBD, as 125 its conformation is very similar to the structures of other RBDs (Figure 2A and 2B).

The structure confirms that RhoD binds the plexin B2 RBD in a mode similar to those of other complexes between Rho-family GTPases and plexin (Bell et al., 2011; Wang et al., 2011; Wang et al., 2012). The GTP analogue GMP-PNP and Mg^{2+} together stabilize the ligand-binding switch I and switch II regions in the active conformation, which make an extensive interface with one side of the beta-sheet of the RBD (Figure 2A and 2B). All the residues in RhoD involved in interacting with the 131 RBD are identical between human and mouse RhoD, suggesting that the cross-species complex that 132 we crystallized is a valid representative of the RhoD/plexin complex. Interestingly, a 133 superimposition of the RhoD/Plexin B2-RBD complex with the RND1/Plexin B1-RBD complex 134 based on the RBD domains shows that the orientation of RhoD and RND1 relative to the RBD 135 domains are slightly different (Figure 2A and 2B). Compared with that in RND1, the switch II helix in RhoD is placed further away from the RBD. This appears to be required to accommodate Phe85, 136 137 which is bulkier than Cys81, the corresponding RND1 residue. This difference leads to different 138 pivots of the two GTPases relative to the RBD, which propagates to a larger difference in the 139 opposite side of the molecule, where the insert helices (α I), a helical segment uniquely present in the 140 catalytic domains of Rho-family GTPases, is located (Figure 2A). In the context of the active dimer 141 of full-length plexin on the plasma membrane, the α I helix faces the membrane (Figure 1D and 1E). 142 This orientational difference of RhoD and RND1 relative to plexin therefore may affect their 143 interactions with the membrane, although it is unclear whether and how that effect is related to the 144 opposite roles of RND1 and RhoD in plexin signaling.

145 To investigate the conformational dynamics of RBD complexes with RND1 and RhoD, we simulated 146 the RBD complexes with RND1 or RhoD, each for three 1-us simulations. In these simulations only 147 the RBD domain of plexin A4 and the catalytic domain of RND1 or RhoD were included. These 148 simulations showed that both complexes are overall stable, with the root mean square deviation (RMSD) of the Ca atoms of the catalytic domains with respect to their initial positions fluctuating 149 around 4 Å when the RBD domain aligned (Figure 2C). By this metric, RND1 appears to be more 150 151 flexible than RhoD relative to the RBD (Figure 2D). The aI helix of RND1 was also more flexible 152 than RhoD with respect to the catalytic domain as a whole in the simulations (Figure 2D and 2E). 153 This analysis is consistent with our finding that the RhoD regulation of plexin activity requires a 154 stable membrane interaction involving the αI helix, but the RND1 function involves little membrane 155 interaction. This simulation finding will be discussed in detail later in this report.

156 *RhoD and RND1 interacts differently with cell membrane*

157 The membrane may play an important role in plexin regulation by Rho-family GTPases, which are 158 located adjacent to the membrane. Previous studies showed that RhoD does not alter the GAP 159 activity of plexin A1 in a solvent environment (Pascoe et al., 2015; Wang et al., 2012). To investigate 160 how the membrane might play a role in plexin regulation mediated by RND1 and RhoD, we 161 simulated plexin A4 dimer in the membrane environment, respectively bound with RND1 and RhoD 162 (Figure 1C). We first constructed a structural model of the transmembrane and the intracellular 163 modules of the plexin A4 dimer with a membrane, primarily using homology modeling based on the 164 resolved structure of the intracellular module of plexin C1 dimer (PDB 4M8N) (Wang et al., 2013). 165 We then added two GTP-bound RND1 molecules to the plexin dimer to bind the RBD domains; the 166 RND1 C-terminal tails each forms an amphipathic helical tail (Thiyagarajan et al., 2004) and serves 167 as a membrane anchor (Figure 1C and 1D). We similarly constructed a plexin dimer model in which 168 each plexin RBD is bound with a (GTP-bound) RhoD, where Cys207 residue of the C-terminal tail is 169 palmitoylated and anchored to the membrane (Figure 1E and Figure 1-figure supplement 1). (In cells 170 the membrane anchor of RhoD is more commonly the geranylated (Hodge and Ridley, 2016) Cys207, 171 but this difference should not affect the results of the simulations. It is worth noting that the 172 construction of these two models was essentially constrained by existing crystal structures. It 173 involved piecing together the plexin dimer structure (in which the RBD domains are resolved) and 174 the complex structures of RBD bound with RND1 or RhoD. As shown in Figure 1C, the positioning 175 of the plexin dimer with respect to the membrane is determined by symmetry, i.e., the two halves of 176 the plexin dimer are identical in terms of their positions relative to the membrane. With exception of 177 the C-terminal loops of RND1 and RhoD, these two models are highly similar prior to simulations.

We simulated the RND1-bound (Figure 3A) and the RhoD-bound (Figure 3B) plexin dimers, each for 179 1 µs three times. In the simulations of the RND1-bound dimer, the amphipathic helices at the C- termini of the RND1 molecules remained anchored to the membrane, and the RND1 linkers between the catalytic domains and the amphipathic helices (residue 189-200) are sufficiently long to not affect the position of the catalytic domains (Figure 3A). The contact area between the membrane and the catalytic domains remains relatively small, with a mean at approximately 200 Å² (Figure 3D and 3E, and Figure 3-figure supplement 1A). The two RND1 catalytic domains largely remained in their initial positions, with the RMSD of the C α atoms with respect to their initial positions fluctuating around 6 Å (Figure 3E).

187 The C-terminal tail of the RhoD is shorter and more arginine-rich than the RND1, which is likely 188 membrane-bound and hence restrains the RhoD catalytic domain to the membrane. In contrast to the 189 RND1-bound plexin dimer, in the simulations of the RhoD-bound plexin dimer, the membrane 190 interactions of the RhoD catalytic domains developed extensive and stable interactions with the 191 membrane in the courses of the simulations (Figure 3D and Figure 3-figure supplement 1A). The 192 contact area of the two RhoD domains with the membrane fluctuated but generally trended upwards. 193 It is apparent that the extent of the membrane interaction is closely correlated with the positioning of 194 the catalytic domains in both the RND1- and the RhoD-bound plexin dimers. With the increase of 195 the membrane interactions, the two RhoD domains deviated substantially from their initial positions, 196 as shown by the RMSD of C α atoms with respect to their initial positions (Figure 3E). The RMSD 197 fluctuation of the RhoD domains was larger than the RND1 domains (Figure 3E), indicating that the 198 differential membrane interactions of RhoD and RND1 lead to their differential positioning and 199 dynamics. Our analysis showed that, for RhoD more than for RND1, the membrane contact area is 200 correlated with the RMSD of the GTPase domain with respect to its initial position (Figure 3F), in 201 agreement with the notion that the membrane interaction modulates RhoD positioning.

Further analysis suggested that RhoD interacts with the membrane with a specific interface involving the α I helix and the α 4 helix (Figure 3C); Arg144, Arg145, His154, and Arg155 in this part of RhoD 204 enjoyed stable interactions with the membrane (Figure 3G). The RhoD membrane-anchoring 205 interface features pronounced positive electrostatic potential that is favorable for membrane 206 interaction (Figure 3G). As shown in Figure 3-supplement 1D, the number of RhoD residues in 207 membrane contact grew in the simulations, and the contact map showed that the membrane contact 208 primarily involved the α I helix (Residue 130–146) and its neighboring region. We also observed the 209 development of enrichment of the negatively charged POPS lipids among the lipids in contact with 210 RhoD in the course of the simulations (Figure 3-figure supplement 1E), in agreement with the 211 electrostatic nature of the membrane interaction of RhoD. The trend of charged lipids becoming 212 enriched in the membrane interfaces with RhoD molecules was also observed (Figure 3-figure 213 supplement 1F) in similar simulations where PIP2 lipids were included in the membrane. In contrast, 214 RND1 interaction with the membrane is much less stable, without a specific membrane interface 215 (Figure 3G) and with fewer residues involved (Figure 3-figure supplement 1D). The positively 216 charged residues in the RhoD membrane interface are almost all replaced in RND1 (Figure 3H), and 217 hence the strong electrostatic feature of RhoD in that region is absent in RND1 (Figure 3G). These 218 observations combined suggest that the tight membrane interaction of RhoD may be attributed to the 219 short C-terminal tail and to the positively charged surface patch, which distinguish RhoD from 220 RND1.

221 The simulations of both the RND1-bound and the RhoD-bound plexin dimer were initiated from 222 highly similar models that integrate structural information in existing crystal structures. In these 223 simulations, the behavior of RND1 and RhoD molecules diverged in terms of their membrane 224 interaction. To ensure that this finding is not associated with a feature of the particular initial models, 225 we performed the following control simulations. We took a typical simulation-generated 226 conformation of the RhoD-bound plexin dimer (in which the RhoD molecules bear extensive 227 membrane interaction) and swapped the RhoD molecules for RND1. In the resulted RND1-bound 228 plexin dimer, the RND1 molecules inherited the extensive membraned interaction. Similarly, we took 229 a typical simulation-generated conformation of the RND1-bound plexin dimer (in which the RND1 230 molecules bear limited membrane interaction) and swapped the RND1 molecules for RhoD. In the 231 resulting system, the RhoD molecules bear little membrane interaction. We then performed three 232 0.5-us long simulations for each of these two systems, hoping that the simulations will reinstall the 233 previously observed pattern of membrane interaction for RND1 and RhoD, despite that the initial 234 structures are of the opposite pattern (We added PIP2 lipids to the membrane in these simulations to 235 better represent the cell membrane). Indeed, in the control simulations, the RND1 membrane contact 236 area dwindled, while the RhoD membrane contact area grew steadily and gradually surpassed the 237 RND1 (Figure 3I, and Figure 3-figure supplement 1B and 1C). We believe that these additional 238 simulations provide important validation to the key observations we obtained with respect to the 239 membrane interactions of RND1 and RhoD. While the trend is clear in these relatively short (0.5 μ s-240 long each) simulations, most likely the simulations have not converged and the trend will become 241 more pronounced if the simulations are extended.

242 The differential membrane interactions lead to different RBD position and dynamics

243 In the plexin dimer, each RhoD or RND1 molecule is located in a space confined by the membrane 244 and the RBD domain and interacts with both simultaneously (Figure 4A and 4B). In the simulations, 245 the RBD interacts with either RhoD or RND1 stably, although RhoD interacts with RBD with a 246 slightly larger interface than RND1 (Figure 4C and Figure 4-figure supplement 1A). In addition to 247 RND1- and RhoD-bound plexin dimers, we simulated plexin monomer and dimer with the RBD 248 domains unoccupied, each for 500 ns. We analyzed the positions of the RBD domain with respect to 249 the GAP domain in all our simulations. The RBD domain appeared to be inherently flexible with 250 respect to the GAP domain as shown in the monomer simulations (Figure 4E and Figure 4-figure 251 supplement 1C). This is suggested by existing crystal structures of plexins, in which the RBD domain 252 exhibited substantial flexibility with respect to the GAP domain (Figure 4F). The interface between RBD and GAP appeared to be reduced by the presence of RhoD but not by the presence of RND1 (Figure 4D, and Figure 4-figure supplement 1B and 1E). The RBD RMSD with respect to its initial position was overall larger for the RhoD-bound than for the RND1-bound plexin dimer (Figure 4E and Figure 4-figure supplement 1C), indicating that RhoD likely displaces the RBD from its native position while RND1 tends to stabilize RBD at that position. Since RBD binds stably with both RND1 and RhoD, the differential RBD positioning and dynamics may likely be attributable to the differential membrane interactions of RND1 and RhoD.

260 *RBD* affects plexin dimerization via the buttress segment

261 The dimerization of plexins is mediated by their dimerization helices that are immediately C-terminal 262 to the juxtamembrane helices (Figure 1B). The interaction between two dimerization helices in the 263 dimer, which resembles coiled-coil interactions, is reinforced by Helix 11 of the GAP domain (Figure 264 1C) (Wang et al., 2013). In crystal structures, Helix 11 is a stable helix, but the segment to its Nterminal is more variable structurally —— it takes the form of a 3-10 or an α helix in some crystal 265 266 structures but in many other structures it is disordered. When it is a 3-10 or an α helix, it becomes an 267 extension of Helix 11 and runs adjacent and in parallel to the dimerization helix, structurally 268 reinforcing the interaction of the two dimerization helices in resemblance to a buttress. Based on this 269 observation we refer to it the buttress segment (Figure 1A and 1B).

The RBD is connected to the plexin GAP domain by two linkers, a C-terminal and an N-terminal linker. The C-terminal linker (Residue 1597-1662) is followed immediately by the buttress segment. This linker is long and partially disordered in crystal structures, especially in the part closer to the buttress segment. This suggests that this linker is conformationally highly flexible. The shorter Nterminal linker (residue 1482-1495) connects RBD to the bulk of the GAP domain and is packed against the buttress segment (Figure 5A and 5B). It is likely that the N and C linkers mediate the 276 regulation of the buttress segment by the RBD since their conformations are expected to be closely 277 coupled with the position of the RBD on one side and with the conformation of the buttress segment 278 on the other.

279 Our simulations showed that the buttress interaction with the dimerization helix is minimal in a 280 monomeric plexin, and this interaction increases substantially in plexin dimers (Figure 5D and Figure 281 5-figure supplement 1A). Importantly, with RhoD binding at the RBD, the buttress interaction with 282 the dimerization helix in the plexin dimer is much reduced compared to that in the RND1-bound 283 dimer or in the dimer where the RBD domains are unoccupied, suggesting that RhoD weakens the 284 buttress interaction with the dimerization helix and potentially destabilizes the plexin dimer. In 285 simulations of the RhoD-bound plexin dimer, the buttress segment lost its helical structure and 286 gradually disengaged the dimerization helices (Figure 5C). In contrast, in simulations of the RND1-287 bound dimer both the helical structure and the interaction with the dimerization helices are much 288 more stable (Figure 5B). The difference is reflected by the smaller contact area of the buttress 289 segments and the dimerization helices in the RhoD-bound system than in the RND1-bound system 290 (Figure 5D and Figure 5-figure supplement 1A). Moreover, the simulations showed that in the 291 RhoD-bound dimer the pair of the dimerization helices was conformationally more variable than that 292 in an RBD-unoccupied plexin dimer, and the dimerization helices in an RND1-bound dimer was less 293 variable than the unoccupied dimer (Figure 5E and 5F, and Figure 5-figure supplement 1B). This is 294 consistent with the notion that RhoD binding destabilizes the plexin dimerization interface while 295 RND1 binding may stabilize the dimer.

Based on these simulation results we suggest that the differential membrane interaction of RND1 and RhoD propagates to the plexin dimerization interface and confers antithetic impact to plexin dimerization through the RBD domain and its N and C linkers (Figure 5B). RhoD binding destabilizes the RBD with respect to the GAP domain, destabilizing the buttress segment with respect to the dimerization interface, and ultimately leads to destabilization of the dimer interface. In
 contrast, by the same RBD-centered route, RND1 binding helps stabilize the plexin dimer.

302 **Discussion**

303 Plexins function in ways similar to a transistor in that they take two inputs and their responses to the 304 primary input of semaphorin are regulated by the secondary input in form of the Rho-family 305 regulatory GTPase binding at the RBD domain. RND1 serves as a promoter of plexin signaling, 306 while RhoD serves as an inhibitor. Our structural and molecular dynamics simulations and analyses 307 suggest that the differential effects of RND1 and RhoD may arise from their differential interactions 308 with the membrane. RND1 interacts with the membrane loosely and non-specifically, while RhoD 309 interacts with the membrane tightly with a specific interface. This difference gives rise to different 310 positioning and dynamics of the RBD domain, which dictates the conformation of the buttress 311 segment adjacent to the dimerization interface of plexin. We further showed that RhoD binding 312 destabilizes the dimerization interface while RND1 binding helps stabilize the interface. In short, we 313 propose an allosteric mechanism that regulates plexin dimerization involving cell membranes, the 314 regulatory GTPases, the RBD domain, and the buttress segment (Figure 5G).

315 Our results on RND1 and RhoD offer a framework for the analysis of plexin regulation by Rho-316 family GTPases. We show that the antithetic roles of RND1 and RhoD result from two seemingly 317 minor differences. First, RhoD furnishes a much shorter C-terminal tail than RND1, and 318 consequently, RhoD is spatially more restrained to the membrane than RND1. Secondly, RhoD 319 features a surface region that is rich in positively charged residue, which serves as the interface with 320 membranes; these positively charged residues are not present in RND1. These two differences 321 determine that RND1 and RhoD interact with the membrane differently, and play different roles in 322 plexin regulation. To experimentally validate or falsify this hypothesis, we suggest testing the effect 323 of altering the C-terminal tails of RND1 and RhoD and the electrostatic properties of the putative 324 membrane interface (Figure 3G). Specifically, mutating RND1 residues (e.g. Leu133, Glu138, 325 Ser140, and Glu150) at the α I or α 4 helices (the putative membrane-contacting region of RhoD) into 326 positively charged arginines or lysines should impair the role of RND1 as a plexin activator and 327 conversely, mutating the lysines and arginines at these two helices of RhoD should impair the role of 328 RhoD as a plexin inhibitor. By the same rationale, lengthening the C-terminal loop of RhoD should 329 impair its inhibitory effect, while shortening the loop of RND1 should impair its activating effect. 330 Likely, combinations of these two sets of modifications to RND1 and RhoD should confer a 331 compound effect.

332 We analyzed the sequences of the Rho-family GTPases and, to our surprise, we found that these two 333 features are indeed correlated. The Rho GTPases with longer C-terminal tails indeed tend to feature 334 more positively charged residues at the putative membrane interface (Figure 6). This suggests that, 335 besides RND1 and RhoD, other Rho-family GTPases may also be involved in regulations of plexin 336 signaling, and that the Rho-family GTPases with short C-terminal tails may likely be down-regulators 337 and the other with long C-terminal tails likely up-regulators. In cell biology, similar to plexin 338 regulation by Rho-family GTPases, there are many other cases in which similar proteins in the same 339 family interact with their target proteins almost identically yet achieve opposite regulatory effects. 340 Simulations are an expedient platform to gain insight into such mechanisms.

In this study, we chose to focus on plexin A4 as a representative system, despite that crystal structures of the intracellular domains are not available for A4. Unlike A4, for those plexins for which better structural data are available, direct functional data of regulation by Rho-family GTPases are lacking. Plexin C1, which is arguably the best structurally characterized plexin in terms of the intracellular domains, is such an example. Even for C1, the structural information is incomplete as the structure of C1 complex with a Rho-family GTPase is not available. It is thus necessary to 347 construct models from other plexin structures regardless of our choice of plexin system. We resorted 348 to homology modeling (see Methods) to construct A4 structures for simulations, considering the high 349 level of sequence (35% or above overall) and structure similarly among the plexin family members, 350 in particular in the dimer interface. The binding mode between class A plexins and Rho-family 351 GTPases is particularly conserved, as shown by the numerous crystal structures, including that of 352 Plexin B2/RhoD presented in this paper. We therefore believe the models of the Plexin A4/RND1 353 and PlexinA4/RhoD complexes are reliable. Moreover, our conclusion concerns mostly inter-domain 354 interactions and thus is less likely to be sensitive to the structural details, as the main driving force is 355 the electrostatic interactions between the GTPases and membrane (Figure 3G), rather than any 356 specific residue-residue interactions arising from a specific conformation. Reassuringly, our findings 357 are supported by a recent study on plexin B1, which (Li et al., 2020) identified the functional importance of the buttress segment (or "activation switch loop" as is referred therein) based on 358 359 analysis of plexin enzymatic turnover, and showed that the segment helps stabilize the dimerization 360 helix when the plexin active site is occupied by Rap.

361 Our results suggest that similar to many other signaling proteins, for plexin the membrane also plays 362 an important role in its regulation. In a membrane environment of a high composition of negatively-363 charged lipids such as POPS, PIP2, and PIP3, plexin signaling is likely more susceptible to negative 364 regulation by RhoD. There are reports that plexin signaling activates the PI3K/AKT pathway, upon 365 which PIP2 lipids in the membrane are phosphorylated and converted to more negatively charged 366 PIP3 lipids (Falkenburger et al., 2010). Our findings raise the question as to whether down-regulation 367 associated with RhoD binding may be part of a negative feedback mechanism for plexin signaling 368 involving the PI3K/AKT pathway. 369

374 Materials and method

375

1. Construction of the simulation systems

This research included eight simulation systems: RBD-RND1 and RDB-RhoD complexes, plexin monomer, plexin dimer with unoccupied RBD, two RND1-bound dimer systems, and two RhoD-bound dimer systems. Except for the RBD-RND1 and RDB-RhoD complexes, which are membrane-free, the other systems included the membrane and plexin transmembrane helix.

381

382 Lacking the crystal structure for plexinA4, we constructed one monomeric structure of the intracellular portion of plexin A4 using homology modeling. The sequence of mouse plexinA4 383 384 was taken from the NCBI website (http://www.ncbi.nlm.nih.gov/protein). The templates were 385 selected according to the SWISS-MODEL searching results (http://swissmodel.expasy.org/) (Bertoni et al., 2017; Guex et al., 2009; Waterhouse et al., 2018), which were mainly the 386 387 intracellular domain including mouse PlexinA1 (PDB entry 3RYT), mouse PlexinA3 (PDB entry 388 3IG3), mouse PlexinB1 (PDB entry 3SU8), and human PlexinC1 (PDB entry 4M8N), 389 respectively. All the homology sequence identities of human PlexinA4 with the mouse PlexinA1, 390 A3, B1, *h*PlexinC1 were higher than 35%. The sequence alignment was done by T-coffee (Llados 391 et al., 2018), and the output alignment file was used to do homology modeling with Modeller 9.17 392 (Benjamin et al., 2014; Fiser et al., 2000). Modeller generated 100 structural models for the query 393 sequence, and the one with the lowest estimated energy was selected for the construction of our 394 simulation systems.

395

396The plexinA4 dimer structure was obtained from superimposing the monomeric model of397plexin A4 onto each protomer of the crystal structure of plexin C1 dimer (PDB entry 4M8N).

398

407

399 We also constructed the complex structure of RND1 with the RBD domain using Modeller 400 9.17. All the template structures selected in this research were downloaded from the Protein Data 401 Bank (PDB) database. The templates for constructing RND1 we selected were the resolved 402 crystal structures PlexinA2 hRND1(PDB entry 3Q3J). The process of the Modeller generating 403 structures and the selection standard were the same as used in constructing plexin structure. We 404 separately resolved the RhoD-RBD complex structure using crystallography. A Palmitoyl group 405 was covalently linked to Cys207 of the C-terminal tail of RhoD to produce a palmitoylated 406 cysteine. This structure was incorporated into the simulation systems.

408 The CharmmGUI website (http://www.charmm-gui.org/) (Jo et al., 2007; Jo et al., 2008; Wu 409 et al., 2014) was used to construct the systems containing the membrane. The membrane in the 410 simulation systems was comprised of heterogeneous lipids. There were 1-Palmitoyl-2-oleoyl-sn-411 glycero-3-phosphocholine (POPC) molecules in the upper leaflet and POPC and negatively-412 charged 1-palmitoyl-2-oleoyl-sn-glycero-3-phospho-L-serine (POPS) molecules with a ratio of 413 7:3 in the lower leaflet for the original dimer systems(Arkhipov et al., 2013; Meer et al., 2008; 414 Zachowski, 1993), and POPC and POPS and phosphatidylinositol (4,5)-bisphosphate (PIP2) 415 molecules with a ratio of 70:25:5 in the lower leaflet in the control dimer systems, so there were 416 negative charges in the inner membrane (Jo et al., 2009).

417

In order to ensure that the simulation results were not associated with the features of the initial models, we built two control simulation systems. We used the last snapshot of a 1-µs simulation of a RhoD-bound plexin dimer, and swapped the RhoD molecules for RND1; similarly, we use the last snapshot of a 1-µs simulation of an RND1-bound plexin dimer, and swapped the RND1 molecules for RhoD. 27 PIP2 molecules were added to the membrane which constitute 5% of the lipids in the inner leaflet. We then performed three 0.5-µs long simulations for each of these two systems.

The monomer system was a cubic box of $120 \times 120 \times 140 \text{ Å}^3$ that contained 198,176 atoms in 425 total, including water molecules and Na⁺ and Cl⁻ ions. The RBD-RND1 and RBD-RhoD systems 426 take the form of a cubic box of $100 \times 100 \times 100$ Å³ that contained 110,932 atoms and 104,447 427 atoms in total, respectively. The plexin dimer system with the RBD domains unoccupied was a 428 cubic box of 190 x 190 x 170 Å³ that contained 639,794 atoms in total. The first RND1-bound 429 plexin dimer system was a cubic box of 190 x 190 x 170 \AA^3 that contained 679,235 atoms in total. 430 The first RhoD-bound plexin dimer system was a cubic box of 190 x 190 x 170 \AA^3 that contained 431 679,086 atoms in total. The control RND1-bound plexin dimer system was a cubic box of 180 x 432 433 180 x 170 Å³ that contained 580,115 atoms in total. The control RhoD-bound plexin dimer system was a cubic box of $180 \times 180 \times 190 \text{ Å}^3$ that contained 648,627 atoms in total. The 434 dimensions of the simulation boxes were chosen so that the minimum distance of any protein in a 435 system was greater than 10 Å to the edge. Na⁺ and Cl⁻ ions were added to maintain physiological 436 437 salinity (150 mM) and to obtain a neutral charge for the system. All the components in the system including POPC, POPS, PIP2, and protein as well as palmitoylated lipid were parameterized 438 using the CHARMM36 force field (Lee et al., 2016) and TIP3P water model (Jorgensen et al., 439 440 1983).

441 The above dimer system with the RBD domains unoccupied system was also used to set up 442 the G-protein-bound dimer system. When the system of two plexin monomer inserted into the 443 membrane was generated, the initial placement of the RND1 molecule bound to RBD of plexin was determined by firstly superimposing one monomer structure in the dimer on the complex of 444 445 RBD bound with RND1 (PDB entry 3Q3J) with the RBD domains aligned, followed by 446 superimposing one RND1 structure on the RND1 in the complex structure encoded 3Q3J. The 447 RND1 structure was placed at the targeting position. Meanwhile, both the GTP molecule and Magnesium (Mg²⁺) ion in the complex (PDB entry 3Q3J) were superimposed on the RND1 448 structure. For the other monomer, the RND1 structure as well as the GTP molecule and ${Mg}^{2+}$ 449 were also placed at the corresponding positions in the same way. Finally, the whole system of the 450 451 RND1-bound plexin dimer inserted into the membrane was set up. The RND1-bound dimer system was placed in a cubic box of 190 x 190 x 170 \AA^3 and 679,235 atoms in total in the system. 452

453 The RhoD-bound dimer system was a cubic box of 190 x 190 x 170 Å³ that contained 679,086 454 atoms in total. Both RhoD and RND1 were GTP-bound in the systems with Mg^{2+} coordinating 455 the GTP binding.

456

457 **2. MD Simulations**

458 Each initial simulation system was equilibrated under NPT ensemble at 1 bar and 300 K for 5 459 ns, after energy minimization (50,000 steps) and a preliminary NVT equilibration (500 ps) with 460 the position restraint applied on the heavy atoms of the protein with a force constant of 10 kJ/mol/Å². Periodic boundary condition (PBC) was imposed on the system to eliminate the 461 boundary effect. A cutoff distance of 12 Å was set for van der Waals interactions and the long-462 463 range electrostatic interactions were treated by the Particle Mesh Ewald (PME) method (Darden 464 et al., 1993). LINCS algorithm (Hess et al., 1997) was used to constrain the covalent bonds involving hydrogen atoms. The time step was set to 2.5 fs. The temperature was controlled by the 465 Langevin thermostat with a collision frequency of 2.0 ps⁻¹ and the Berendsen barostat (Berendsen 466 et al., 1984) was used to control the pressure at 1.0 atm. All MD simulations were performed 467 468 using Gromacs 5.1.3 on Tianhe Supercomputer. Each of the simulations of the monomer and the 469 dimer system with unoccupied RBD domains was 0.5-µs long, and each of the simulations of the 470 RND1- and RhoD-bound dimer was 1-µs long.

471

472 **3. Trajectories Analysis**

473

3.1 Protein-protein Contact Area Calculation

474

All the protein-protein contact areas were calculated using Gromacs command "gmx sasa".

475

476 **3.2 RMSD Analysis**

477 **RMSD of an RND1 or RhoD as an indicator of its position relative to the plexin**

478 The RMSD calculation was carried out by first aligning the system by the C α atoms of the 479 GAP domain of the plexin protomer to which the GTPases is bound to, and then the RMSD was 480 calculated using the C α atoms of the GTPase with respect to their initial positions in the aligned 481 simulation system. 482

483

RMSD of RND1 or RhoD as an indicator of its position relative to the RBD domain

484 The RMSD calculation was carried out by first aligning the system by the C α atoms of the 485 RBD domain of the plexin protomer to which the GTPases is bound to, and then the RMSD was 486 calculated using the C α atoms of the GTPase with respect to their initial positions in the aligned 487 simulation system.

488 489

RMSD of RBD as an indicator of its position relative to the corresponding GAP domain

490 The RMSD calculation was carried out by first aligning the system by the C α atoms of the 491 GAP domain of the same plexin protomer, and then the RMSD was calculated using the C α 492 atoms of the RBD with respect to their initial positions in the aligned simulation system.

493

494

RMSD of the dimerization helix as an indicator of the stability of the dimer interface

495 The dimerization helices were first aligned using their C α atoms, and then the RMSD was 496 calculated using the C α atoms with respect to their initial position.

497

498 **3.3 The metric for protein-membrane interaction**

For each residue of the protein in each simulation snapshot, the number of any lipid molecules within 5 Å of any atom of the residue is calculated. This number was averaged over each simulation (with the first $0.3 \ \mu s$ of the simulation ignored) for each protein residue as a metric for the residue's membrane interaction.

503

504 **4. Sequence Alignment**

505 The sequences of human RND1 and RhoD were downloaded from the NCBI website. The 506 sequence alignment of the GTPases of the Rho family was performed using the UniProt website 507 (https://www.uniprot.org/).

- 508
- 509 **5. Protein expression and purification**

510 The coding region of the intracellular region of mouse plexin B2 with the juxtamembrane 511 region removed (residues 1274-1842) was cloned into a modified pET-28(a) vector (Novagen) 512 that encodes an N-terminal His6-tag followed by a recognition site for human rhinovirus 3C 513 protease. The plasmid was transformed into the E. coli strain ArcticExpress (DE3) (Stratagene). 514 ArcticExpress (DE3) carrying the expression plasmid was cultured at 37 °C in 100~120 mL LB 515 medium in the presence of Gentamycin overnight. Bacterial cells were scaled up at 30 °C to reach 516 OD600 2.0 in TB medium. Protein expression was induced by 0.2 mM IPTG at 10°C overnight. 517 Cells were harvested by centrifugation and resuspended in Buffer A containing 10 mM Tris (pH 518 8.0), 500 mM NaCl, 5 % glycerol (v/v), 20 mM Imidazole, and 3 mM β-mercaptoethanol. Cells 519 were lysed with a Avestin C3 disruptor (Avestin) and subjected to centrifugation. The plexin 520 protein in the supernatant was captured using a 1 mL HisTrap FF column (GE Healthcare) and 521 eluted by Buffer B containing 10 mM Tris (pH 8.0), 500 mM NaCl, 5 % glycerol (v/v), 250 mM 522 Imidazole, and $3 \text{ mM} \beta$ -mercaptoethanol. The protein was treated with recombinant human 523 rhinovirus 3C protease at 4 °C overnight to remove the N-terminal His6-tag. The tag-removed 524 protein was loaded to a Resource Q anion-exchange column (GE Healthcare) and eluted with a 525 linear NaCl gradient (10 mM to 300 mM). Fractions containing plexin B2 were pooled and 526 subjected to size exclusion chromatography with a Superdex 200 GL 10/30 column (GE 527 Healthcare) equilibrated with Buffer C containing 20 mM Tris (pH 8.0), 150 mM NaCl, 10% 528 glycerol (v/v), and 2 mM DTT. Purified proteins were concentrated and stored at -80 °C.

529

530 The coding region of human RhoD (residues 8–194) with the Q75L mutation, which renders 531 the protein catalytically dead and therefore does not hydrolyze GTP, was cloned into the above-532 mentioned modified pET-28(a) vector. The plasmid was transformed into the bacterial strain 533 BL21 (DE3). Protein expression was induced by 0.2 mM IPTG at 16 °C overnight. The protein 534 purification procedure was similar to that for plexin B2, except that all the buffers contained 2 535 mM MgCl₂. The RhoD protein with the Hist6-tag removed was subjected to the final purification 536 step with a Superdex 75 GL 10/30 column with Buffer D containing 20 mM Tris (pH 8.0), 537 250 mM NaCl, 10 % glycerol (v/v), 2 mM MgCl₂, and 2 mM DTT.

539 To load the protein with GMP-PNP (guanosine 5'-[β , γ -imido]triphosphate) for crystallization, 540 the purified RhoD protein was incubated with GMP-PNP at 20-fold molar ratio to the protein in 541 the exchange buffer containing 20 mM Tris (pH 8.0), 250 mM NaCl, 5 % glycerol (v/v), 7.5 mM 542 EDTA, and 1 mM DTT at RT for 2 hours. After the incubation, 20 mM MgCl₂ was added to stop 543 the exchange reaction. The protein was then subjected to gel filtration chromatography on a 544 Superdex 75 GL 10/30 column equilibrated with Buffer D to remove excess GMP-PNP.

545 546

6. Crystallization, X-ray data collection and structure determination

547 Plexin B2 and GMP-PNP-loaded RhoD were mixed at 1:1 molar ratio in a buffer containing 10 548 mM Tris (pH 8.0), 150 mM NaCl, 10 % glycerol (v/v), 2 mM MgCl₂, 2 mM TCEP, and 100 µM 549 GMP-PNP to form the complex. The total protein concentration of the complex for crystallization 550 was 6 mg/mL. The complex was crystallized initially at 20 °C in 0.2 M MgCl₂ and 20 % 551 PEG3350 (w/v) in sitting-drop 96-well plates. Crystals large enough for data collection were 552 grown for over a month with sitting-drop or hanging-drop vapor diffusion at 20 °C in 0.2 M 553 MgCl₂, 22 % PEG3350 (w/v), and 100 mM MIB (pH 6.8, sodium malonate, imidazole, and boric 554 acid mixed at 2:3:3 molar ratio). Crystals were cryo-protected using the crystallization buffer 555 supplemented with 25% glycerol and flash cooled in liquid nitrogen. Diffraction data were 556 collected at 100 K at the beamline 19ID at the advance photon source (Argonne, IL). Data were 557 indexed, reduced and scaled with the software HKL2000 (Otwinowski and Minor, 1997). 558 Molecular replacement using RND1 (PDB ID: 2REX) as the search model with the program 559 phaser (McCoy et al., 2007) found two copies of RhoD in the asymmetric unit. However, 560 repeated search using various full-length intracellular region of plexin models failed to yield any 561 solution. In the end, the RBD of Plexin B1 (PDB ID: 2REX) as the search model led to the 562 solution of two copies of Plexin B2-RBD in the asymmetric unit. It is likely that the full-length 563 intracellular region of Plexin B2 was degraded during the prolonged incubation at 20 °C in the 564 crystallization drops, which separated the RBD from the rest of the protein. The RBD formed the 565 complex with RhoD, which crystallized at the end. The initial model from molecular replacement 566 was manually modified in Coot (Emsley et al., 2010) and refined using Phenix (Liebschner et al., 567 2019). The density clearly showed that the two RBD domains were formed a domain-swapped 568 dimer, with the swap occurring between residues 1509 and 1510. As a result, the N-terminal 569 segment (residues 1463-1509) from the first molecule and the C-terminal segment (residues 570 1510-1565) from the second molecule pack together to form one RBD, and vice versa. The 571 conformation of the RBD formed in this manner is very similar to other RBD structures in the 572 database, and its binding mode with RhoD is very similar to that in other RhoGTPase/RBD 573 complexes. This domain-swapped dimer cannot form in the context of the intact plexin, and 574 therefore is unlikely have any biological significance. The refined structure were validated by 575 using Molprobity as implemented in Phenix (Williams et al., 2018). The data collection and 576 structure refinement statistics are summarized in Supplementary File 1.

577

578 FIGURE CAPTIONS

579 Figure 1. Plexin architecture, dimerization, and GTPase binding of the RBD domain. (A) 580 Components of a plexin molecule. Each RBD domain is connected with a GAP domain by the N and 581 C linkers. (B) Architecture of the semaphorin-induced plexin dimer. A buttress segment is positioned 582 between the RBD domain and the dimerization helix. Helix 11 is C-terminal to the buttress. The 583 activation segments are held in the active conformations by the dimerization helices in trans. A Rap 584 GTPase is bound to each GAP domain as a substrate at the active site. (C) The RND1- or RhoD-585 bound plexin dimer systems simulated in this study. The extracellular portions of the dimers were 586 excluded. (D) and (E) Structural basis of RND1 stabilization and RhoD destabilization of the plexin 587 dimer according to this study. The key difference is that the catalytic domain of RND1 is relatively 588 detached from the membrane.

590	Figure1-figure supplement 1. RhoD binding with plexin RBD domain and anchoring to the
591	membrane. As shown, an RBD-bound RhoD is anchored to the membrane in our simulations by
592	embedding the palmitoylated Cys207 at the C-terminal tail of the RhoD into the membrane.
593

595

596 Figure 2. Crystal structure of the RhoD/plexin B2-RBD complex. (A) Overall structure of the 597 RhoD/plexinB2-RBD complex based on the domain-swapped dimeric structure (Figure 1-figure 598 supplement 1). The structure of RND1/plexin B1-RBD complex (PDB ID: 2REX) is superimposed 599 based on the RBD for comparison. (B) Expanded view of the binding interface between RhoD and 600 plexin B2-RBD. (C) The Ca RMSD of the RND1 and RhoD catalytic domains and their respective aI 601 helices with respect to the initial positions in simulations of the RND1-RBD and RhoD-RBD 602 complex structures (three 1-µs long simulations for each system). In calculating the RMSDs, the RBD domains were aligned. (D) Multiple snapshots of the aI helix in the simulations (with the RBD 603 604 aligned). As shown, the aI of RND1 appears more flexible in the simulations. (E) The RMSD data 605 shown in Panel C represented in violin plots; the average and RMSD of the distributions are labeled. 606 Consistent with the visualization shown in (D), RND1 appears to be more flexible conformationally 607 when bound with RBD.

Figure 2-figure supplement 1. Two orthogonal views of the asymmetric unit of the RhoD/plexin
B2-RBD complex crystal. The two copies of the RBD, colored blue and cyan respectively, form a
domain-swapped dimer, which binds two RhoD molecules (magenta).

612

613

614

Figure 3. Plexin-bound RND1 and RhoD interact with the membrane differently. (A) and (B) 615 616 Representative snapshots of the simulations of RND1- and RhoD-bound plexin dimer. (C) Close-up 617 view of the membrane interaction of RhoD bound with the plexin dimer. Primarily the membrane 618 interface consists of the positive-charged residues of RhoD at the α 4 and the α I helices. (D) 619 Distributions of the membrane contact area of RND1 and RhoD bound with the plexin dimer. The 620 data was compiled from three simulations each for the RND1- or RhoD-bound dimers. The average 621 and RMSD of each distribution are shown. The occurrence of apparent negative contact area is due 622 to irregularity of the solvent-area program in cases of two objects being adjacent but not in contact 623 with one another. (E) The time series of the membrane contact area of RND1 or RhoD in 624 juxtaposition with the time series of the RMSD of the RND1 or RhoD catalytic domains with respect 625 to their initial positions in two representative simulations. (F) Scatter plots of the membrane contract 626 area and RMSD data shown in (E). As shown, the correlation is stronger for RhoD than for RND1. 627 (G) Upper panels: the membrane contact residues of RND1 and RhoD indicated by color coding (the color-coding indicates the number of lipid residues within 5 Å of the residue average in all 628 629 simulations of the RND1- or RhoD-bound plexin dimer); lower panels: the surface electrostatic 630 properties of RND1 and RhoD around their respective membrane-contacting regions. (H) Sequence

631 alignment of RND1 against RhoD showing that 1) the positively-charged membrane-contacting 632 residues of RhoD are mostly not conserved in RND1, and 2) the C-terminal tail of RhoD is much 633 shorter than that of RND1. The color-coding of the membrane-contact residues is inherited from (G). 634 (I) RND1 and RhoD membrane contact areas obtained from the control simulations of plexin dimer, in which RND1 molecules were initiated at positions with large membrane contact while RhoD 635 636 molecules were initiated at positions with little membrane contact (marked by the dashed lines). 637 Further data from these control simulations are shown in Figure 3-figure supplement 1B and 1C. The 638 average and RMSD for each distribution are shown.

639

640 Figure 3-figure supplement 1. Additional data on RND1/RhoD-membrane contact and charged 641 lipid enrichment. (A) Distributions of the membrane contact area of RND1 and RhoD bound with 642 the plexin dimer. The data was from three simulations each of the RND1- and RhoD-bound dimers; 643 each system contained two RND1 or RhoD molecules, hence the six sets of data. The compiled data 644 are shown in Figure 3D. (B) The membrane contact area or RND1 or RhoD from the three 645 simulations each of the RND1- and RhoD-bound dimers; each system contained two RND1 or RhoD 646 molecules, hence the six sets of data, respectively. The initial positions of RND1 were inherited from 647 the end of a RhoD-bound plexin dimer simulation, with extensive RND1-membrane contact (the dashed line). Conversely, the initial positions of RhoD were inherited from the end of an RND1-648 649 bound plexin dimer, with limited RhoD-membrane contact (the dashed line). As shown, the RND1 650 membrane contact area generally decreased while the RhoD membrane contract area increased in the 651 simulations. (C) The membrane contact area data (B) shown in violin plots. The left and the right 652 regulatory GTPases were shown separately. The left panel is shown in Figure 3I and here again for 653 completeness. (D) RND1/RhoD-membrane contact map in a simulation of RND1-bound plexin 654 dimer and another of RhoD-bound plexin dimer. The lower panels showed the residue contact maps,

and the upper panel shows the total numbers of residues as functions of time. (E) POPS (negatively
charged) lipids (red) are enriched at the RhoD interface (left panels); The percentage of POPS
relative to all lipids in the interface is consistently higher than the 30% average (right panel). This is
a plexin dimer system with two RhoD molecules, but membrane imprint for only one is shown
because the other RhoD molecule bears much less membrane contact. (F) POPS (red) and PIP2
(green) charged lipids are enriched at the RhoD interfaces (left panels) in simulations. The number of
lipid charges in interaction with RhoD increased in the simulation (right panel).

662

663

664

665 Figure 4. RND1- and RhoD-bound RBD domains are positioned differently with respect to 666 their respective GAP domains. (A) RhoD-bound plexin dimer. (B) A close-up of a part of the 667 plexin dimer illustrating the relative positions of the membrane, the RhoD (or RND1) GTPase 668 (purple), the RBD domain (blue), the GAP domain (green), and the dimerization helices (yellow). (C) 669 The RBD contact area of RND1 and RhoD, together with the relative flexibility of RND1 or RhoD 670 relative to the respective RBD domains in terms of RMSD of the catalytic domains with the RBD 671 domains aligned. The RBD complexes of both RND1 and RhoD appear stable. The data sets were 672 compiled from three 1-µs long simulations each for RND1- and RhoD-bound plexin dimer; the 673 individual distributions are shown in Figure 3-figure supplement 1D. As in similar panels, the 674 average and RMSD for each distribution are shown. (D) The contact area of the RBD domains with 675 their respective GAP domains. In addition to simulations of the RND1- and RhoD-bound plexin 676 dimers, simulations of the plexin dimer and monomer with the RBD domains unoccupied are also

677 included. RhoD-binding appears to moderately reduce the RBD-GAP contact area. The individual 678 data sets from the simulations are shown in Figure 3-figure supplement 1E. (E) RBD flexibility 679 relative to the GAP domain indicated by RMSD of the RBD domain measured with the GAP domain 680 aligned. The data suggest that RND1-binding stabilizes the RBD conformation and RhoD-binding 681 destabilizes it. The data from simulations of the plexin monomer and dimer with unoccupied RBD 682 suggests that the RBD domain is inherently flexible relative to the GAP domain. The individual data 683 sets from the simulations are shown in Figure 3-figure supplement 1F. (F) Conformations of the RBD 684 domain relative to the GAP domain in existing crystal structures of plexins. The GAP domain is 685 aligned in generating this figure.

686

687 Figure 4-figure supplement 1. Additional data on RMSD and domain-domain contact. (A) The 688 RBD contact area with RND1 and RhoD, and RMSD of the RND1 and RhoD catalytic domains with 689 the RBD domains aligned from 3 1-µs simulations each for RND1- and RhoD-bound plexin dimer. 690 (B) The contact area of the RBD domains with their respective GAP domains. In addition to the six 691 simulations of the RND1- and RhoD-bound plexin dimers, three simulations each for RBD-692 unoccupied plexin dimer and RBD-unoccupied monomer are also included. The compiled data are shown in Figure 4D. (C) RBD flexibility relative to the GAP domain indicated by RMSD of the 693 RBD domain measured with the GAP domain aligned. (B) and (C) represent the same sets of 694 695 simulations and the same data in compiled form are shown in Figure 4D and 4E. (D) RND1 and 696 RhoD contact with the RBD domain in a simulation of RND1-bound plexin dimer and another of 697 RhoD-bound plexin dimer. The lower panels showed the residue contact maps, and the upper panel 698 shows the total numbers of residues as functions of time. (E) RBD contact with the GAP domain. 699 These data in Figure 3-figure supplement 1D, Figure 4-figure supplement 1D and 1E together 700 showed that in the simulation of RhoD-bound plexin dimer, RhoD interaction with the membrane

developed, in concert with the weakening of the RBD-GAP interaction. The analysis is consistentwith the notion that RND1 interaction with the membrane is limited.

703

704

705

706 Figure 5. Interaction between the buttress segment and the dimerization helices. (A) RhoD- or 707 RND1 bound plexin dimer. (B) Close-up of the RND1-bound dimer centered at the dimerization 708 helices (yellow). The buttress segments (red), Helix 11 (green), the RBD domains (blue), the N 709 (orange) and C (cyan) linkers of the RBD domains, and the activation segments (purple) are shown. 710 (C) A similar close-up of the RhoD-bound dimer. (D) Contact area of the buttress segment with the 711 dimerization helix. As shown, RND1-binding moderately raises the contact area, and RhoD reduces 712 the contact area. The individual data sets from the simulations are shown in Figure 3-figure 713 supplement 1G. (E) The RMSD of the dimerization helices in plexin dimers as a measurement of the 714 stability of the dimerization interface. RhoD-binding clearly destabilizes the dimerization interface. 715 The individual data sets from the simulations are shown in Figure 3-figure supplement 1H. The 716 average and RMSD for each distribution are shown. (F) Snapshots of the dimerization helices. As 717 shown, the dimerization helices are more flexible with respect to one another in the RhoD-bound 718 plexin dimer. (G) A schematic summary of the mechanism by which RhoD and RND1 binding 719 regulate plexin dimerization.

Figure 5-figure supplement 1. Additional data on RMSD and the buttress-dimerization helices contact. (A) Contact area of the buttress segment with the dimerization helix in three simulations each for RBD-free, RND1-bound, RhoD-bound dimers and for plexin monomer. (B) The RMSDs of the dimerization helices in plexin dimers as a measurement of the stability of the dimerization interface. It represents three simulations each for RBD-free, RND1-bound dimers. This panel represents all of the dimer simulations represented in S4B, S4C and S5A. The compiled data are shown in Figure 5E.

Figure 6. The charge distribution at the putative membrane interface of Rho-family GTPases. (A) Sequence alignment of Rho-family GTPases at the region of the putative membrane interface; red denotes negatively charged residues and blue denotes positively charged residues. All members of the Rho family are included in this analysis with exception of RHBT1, RHBT2, and RHBT3, which furnish another domain C-terminal to the catalytic domain. (B) The number of positively- and negatively-charged residues at the membrane interface. The protein name and the number of residues of its C-terminal tail are marked next to each data point herein. Long and short C tails are also color-coded.

741 Supplementary File 1. Diffraction data and structure refinement statistics.

742 Supplementary File 1 includes the diffraction data and refinement statistics of the crystal structure.
